Task Force Report from the EAACI Ocular Allergy Interest Group on Diagnosis and Management of Ocular Allergy.

Accepted for publication 20 July 2012

DOI:10.1111/all.12009

Edited by: Thomas Bieber

Ocular allergy is a localized allergic condition that is observed as the only or dominant presentation of an allergic sensitization, or is associated with rhinitis. It is not a single clinical entity, but includes several conditions with different pathogenesis, hypersensitivity mechanisms, diagnostic criteria, and management. Ocular allergies are encountered daily in the physician’s office. Approximately 15–20% of the world population is affected by some form of allergic disease; ocular symptoms are estimated to be present in 40–60% of allergic patients (1) and contribute significantly to poor quality of life (2–4). Most of the available prevalence data encompass both ocular and nasal symptoms, making it impossible to separate ocular allergy from allergic rhinitis. Moreover, the frequently confusing nomenclature makes estimations of prevalence difficult.

The purpose of this position paper is to unify the nomenclature and classification of ocular allergies, in order to facilitate the exchange of information and knowledge on diagnosis and management between allergists and ophthalmologists. The existing evidence for treatment options was evaluated using the SIGN criteria (5).

Classification and nomenclature
The ocular allergy nomenclature is based either on clinical signs and symptoms (Table 1) or on pathophysiology, according to the different hypersensitivity mechanisms introduced by Gell and Coombs. In 2001, the European Academy of Allergy and Clinical Immunology (EAACI)
introduced a revised nomenclature that proposed a distinction between allergic and nonallergic hypersensitivity reactions: allergic diseases were further divided into IgE- and non-IgE-mediated hypersensitivities (6). This was validated by the Nomenclature Review Committee of the World Allergy Organization (WAO) (7), who proposed that the nomenclature could be used independently of the target organ or patient age group.

Here, we propose a new classification for ocular allergic disorders (Fig. 1). If allergic ocular hypersensitivity is suspected, identification of the immunological mechanism(s) is justified and potential immunomodulatory treatment can be considered. In contrast, in nonallergic ocular hypersensitivities, different therapeutic strategies should be considered.

A classification based on both pathophysiology and the evolution of the symptoms has been proposed (8). According to the Allergic Rhinitis and its Impact on Asthma (ARIA) document (9), symptoms should be considered as intermittent or persistent, and mild, moderate, or severe according to their evolution and severity. To adapt this classification to ocular hypersensitivity disorders, some points must be considered: these are outlined in Tables 2 and 3.

### Clinical entities
Seasonal allergic conjunctivitis (SAC) is a typical IgE-mediated allergic reaction, usually associated with rhinitis. It is more prevalent from the spring to fall seasons when pollen levels are high. The hallmark symptom is intermittent itching; however, tearing, conjunctival redness, eyelid swelling, and small papillary hypertrophy of tarsal conjunctiva are common but nonspecific signs. Signs and symptoms arise and subside depending on the patient’s exposure to the offending allergen(s). An accurate medical history followed by allergy testing may identify the specific sensitization (see Investigation of ocular allergy).

Perennial allergic conjunctivitis (PAC) is an IgE-mediated reaction to allergens that are present all year-round, such as dust mites, animal dander, and molds, or due to multiple sensitizations. It is characterized by the same signs and symptoms as SAC (Fig. 2A); however, PAC is a chronic condition, with persistent, frequently mild symptoms, enhanced by higher or longer exposure to allergens and exacerbated by nonspecific irritating factors. Neither SAC nor PAC has corneal involvement; however, they affect the patient’s quality of life and have a significant socioeconomic impact (2–4, 10).

Vernal keratoconjunctivitis (VKC) is a persistent and severe form of ocular allergy that affects children and young adults, usually in warm climates. Vernal keratoconjunctivitis typically appears in boys between the age of 4–12 years (sex ratio, 3/1) and disappears after puberty. The IgE-mediated mechanism found in approximately 50% of patients does not completely explain the severity and the clinical course of this disease, which is related to a T-cell-mediated responses, massive eosinophil infiltration and activation, and nonspecific hyper-reactivity. Intense itching, tearing, and photophobia are the typical symptoms of VKC. Disease exacerbation can be triggered either by allergen re-exposure or, more frequently, by nonspecific stimuli such as sunlight, wind, and dust. The tarsal form of VKC is characterized by irregularly sized hypertrophic papillae, leading to a cobblestone appearance of the upper tarsal plate (Fig. 2B). Asymmetric tarsal involvement is not unusual. The limbal form is characterized by transient, multiple limbal, or conjunctival gelatinous yellow-gray infiltrates superposed with white points or deposits, known as Horner–Trantas dots (degenerating eosinophils and...
epithelial cell debris) and papillae at the limbus, which may appear thickened and opacified for 360° (Fig. 2C,D). Punctate keratitis, epithelial macroerosions, ulcers (Fig. 2E), and plaques (Fig. 2F) are signs of corneal involvement and resolve with different levels of scarring. The clinical presentations of VKC differ between western (tarsal forms) and subtropical countries (limbal form, also named endemic tropical limboconjunctivitis) (11).

Atopic keratoconjunctivitis (AKC) is a persistent inflammatory, bilateral condition involving the eyelids, the conjunctiva, and possibly the cornea and can be defined as the ocular manifestation of atopic dermatitis. IgE-, Th2-, and Th1-mediated mechanisms are involved in the pathogenesis. Typical AKC manifestations may occur in patients without definite skin involvement. The hallmark sign is eczematous lesion of the eyelid, which tends to thicken, indurate, and fissure (Fig. 2G). Atopic keratoconjunctivitis may be associated with *Staphylococcus aureus* colonization of the eyelid and meibomian gland dysfunction. The conjunctival redness and chemosis affect predominantly the inferior fornix and palpebral conjunctiva. Similar to VKC, the limbus and the cornea can be involved. Generally, AKC emerges in young adults and continues through the fifth decade of life, with a peak incidence between the age of 30–50. Complications can include conjunctival fibrosis, herpes simplex keratitis, keratoconus, retinal detachment, or cataracts, leading to sustained deterioration of vision. An accurate medical history followed by allergy testing may identify sensitization to specific allergens (see Investigation of ocular allergy).

Giant papillary conjunctivitis (GPC) is a nonallergic hypersensitivity inflammation of the ocular surface, most frequently to contact lenses, ocular prostheses, postoperative sutures, and scleral buckles. The early stages of GPC may be asymptomatic, but initial signs can be observed by slit lamp examination (Fig. 2H). In the case of contact lenses, progression to foreign body sensation, itching, blurred vision, increased mucus production, and increasing intolerance may necessitate discontinuation.

Contact blepharoconjunctivitis (CBC) is an allergic/irritant reaction to different substances applied to the eyelid skin or the conjunctival SAC. The most prominent symptoms are itching and burning of the eyelid. Contact blepharoconjunctivitis is characterized by edema, eyelid skin redness, eczema or lichenification, conjunctival redness, and papillae (Fig. 2I). Eczema on the eyelid skin and absence of conjunctival hyperemia indicate that the irritant has been in contact only with the eyelid.

Special clinical entities

Acute allergic conjunctivitis is a severe, immediate hypersensitivity reaction, lasting from one to three days, and characterized by intense conjunctival chemosis, eyelid redness and edema, eye watering, and itching. It can be mono- or bilateral and caused by IgE-mediated, non-IgE-mediated, or toxic reactions. It can be also related to food- or drug-induced systemic allergic reaction (12).

Occupational allergic conjunctivitis is an IgE-dependent allergic reaction to airborne substances in the workplace (13).

Drug-induced conjunctivitis is a persistent or chronic conjunctivitis, also referred to as conjunctivitis medicamentosa. A toxic reaction may occur following instillation of eye drops, such as topical antiglaucoma agents, mydriatics, or alpha-adrenergic agonists commonly used as decongestants in over-the-counter anti-allergy eye drops (14). Topical antibiotics, eye drops containing herbal extracts, and preservatives, such as benzalkonium chloride, thimerosal, parabens, and ethylenediaminetetraacetic acid (EDTA), may cause either a toxic reaction or a cell-mediated hypersensitivity response. The condition is characterized by an intense and persistent follicular reaction, associated with mild to intense hyperemia. The lacrimal puncta may be swollen or occluded by a cellular infiltrate with a consequent epiphora. The cornea is often involved as a diffuse punctate keratitis. Eyelid skin may be involved with erythema, swelling, and excoriations.

Irritant conjunctivitis, also known as toxic or mechanical conjunctivitis, is frequently confused with allergy. It is the result of destruction of junctures between epithelial cells, and epithelial cell toxicity following single or repeated exposure to chemical substances. A careful medical history and examination can exclude an allergic etiology. Clinical features are similar to drug-induced conjunctivitis.

Epidemiology

There are insufficient data to objectively evaluate the incidence of ocular allergies. To date, only the epidemiology of allergic rhinoconjunctivitis (ARC) has been well studied. According to the ISACA study (International Study Asthma and Allergies in Childhood), ARC affects 1.4–39.7% of children and adolescents. The incidence and prevalence of ARC increase from infancy and peaks in childhood and adolescence (15). In 80% of cases, symptoms develop before the age of 20 years. According to ARIA, seasonal ARC affects 3–42% of the population (depending on different climatic conditions and age groups), with persistent ARC affecting 1–18% (9). In a study of 458 children affected by rhinitis (316), asthma (324), and eczema (149), the prevalence of allergic conjunctivitis was 42%, 24%, and 30%, respectively (16). 137 (30%) had allergic conjunctivitis, of whom 97% also had allergic rhinitis, 56% asthma, and 33% eczema.

In the NHANES III survey with a sample size of 20 010, 40% of the population reported at least one ocular allergy symptom (17). Ocular allergy was twice as common as allergic rhinitis (18). The most common form was SAC. On the other hand, the prevalence of PAC seems to be underestimated by both ophthalmologists and allergists (19). In a study of 19 325 subjects, PAC was associated with coexisting mite allergy in 46% of patients with allergic rhinitis (20).

Vernal keratoconjunctivitis is a rare disease in western countries. The estimated prevalence in Europe is 3.2/10 000, whereas it is almost endemic in subtropical countries (21). It represents 3–46% of ocular allergies (10). Warm climates and sun exposure probably explain the characteristic north–south gradient of prevalence.

Atopic keratoconjunctivitis is a rare disease, and its prevalence is not clear. Whereas ocular involvement is seen in 25–40% of patients with atopic dermatitis, AKC is probably much less frequent. The reported rates range from 1 to 40% of ocular allergies, which probably reflects the lack of a clear definition of this disease (10, 17).
Pathophysiology

IgE-mediated ocular allergy: seasonal allergic conjunctivitis and perennial allergic conjunctivitis

Specific IgE-mediated conjunctival mast cell activation induces the immediate conjunctival allergic response. This lasts 20–30 min, as demonstrated by specific conjunctival allergen challenge (CAC) (22), and is characterized by increased levels of histamine, tryptase, prostaglandins, and leukotrienes in the tears (23). Conjunctival mast cells are 100% tryptase+ and chymase+ and express IL-4, which plays a key role in allergy, promoting T-cell growth, Th2 cell differentiation, and IgE production (24). The late-phase conjunctival allergic response, characterized by infiltration of inflammatory cells, occurs few hours after the first mast cell activation and expression of adhesion molecules (25). Activated mast cells also release several cytokines that stimulate epithelial cells and fibroblasts to produce pro-inflammatory cytokines and chemokines (26), leading to persistent conjunctival inflammation.

Seasonal allergic conjunctivitis patients have a predominant Th2 phenotype (27), but also have a reduced expression of epithelial cell adhesion proteins and cytoskeletal elements, which suggests a reduced ability of the epithelium to protect itself against penetration of the allergen (28).

IgE- and/or non-IgE-mediated ocular allergy: vernal keratoconjunctivitis and atopic keratoconjunctivitis

Vernal keratoconjunctivitis is a persistent and severe form of ocular allergy, characterized by massive infiltration of T cells, macrophages, neutrophils, and especially eosinophils. It can be considered as a severe persistent late-phase reaction (29). It is unclear why the incidence varies with age and geographical region.

Increased numbers of CD4+ Th2 cells, increased expression of costimulatory molecules, and multiple cytokines and chemokines have been described in VKC. These act concomitantly to induce local production of IgE (30), in the pathogenesis of the corneal involvement and tissue remodeling (31–34). Direct activation of allergen-specific T cells by antigens or direct activation of dendritic cells may be alternative pathways for initiating the reaction without evidence of specific IgE sensitization (35). In fact, specific
IgE are identified in only 50% of patients (36), supporting the concept that non-IgE-mediated activation pathways are present. In addition, several enzymatic systems, metalloproteases, and their inhibitors may be activated, contributing to structural cell activation and tissue remodeling (37). Nonspecific hyper-reactivity is another typical aspect, which is, in part, due to the altered expression of neuroreceptors and neurotransmitters (38).

Atopic keratoconjunctivitis is the ocular manifestation of atopic dermatitis. Although 45% of patients do not have any specific sensitization, high serum IgE level and polysensitization are common findings in AKC (39). High levels of multiple cytokines and chemokines have been detected in tears, suggesting that both Th1 and Th2 responses may be activated (40, 41). Atopic keratoconjunctivitis is associated with qualitative and/or quantitative alterations of the mucous component of the tear film, causing mucus discharge, epithelial disease, dry eye signs and symptoms, and the lower stability of the tear film (42). It is also possible that mechanisms related to the activation of innate immunity receptors (Toll-like receptors) play an active role in the chronic inflammatory response (43).

Non-IgE-mediated ocular allergy: contact blepharoconjunctivitis

Contact blepharitis or blepharoconjunctivitis is related to a contact T-cell-mediated delayed hypersensitivity reaction to haptens (incomplete antigens), which become immunogenic only after they bind to tissue protein (14).

Ocular nonallergic hypersensitivity: giant papillary conjunctivitis

Giant papillary conjunctivitis is caused by two factors: a repeated mechanical stimulus and an abnormal conjunctival inflammatory response. Microtrauma of the conjunctiva can be caused by all types of contact lenses. Lens design, polymer constitution, wearing period, and fitting characteristics can influence the development of GPC. The mechanical irritation may stimulate the recruitment of dendritic cells, potentially enhancing antigen presentation and immune responsiveness (44).

Investigation of ocular allergy

Three types of diagnostic investigations are currently used when the initial clinical assessment (history, signs, and symptoms) is suggestive of an ocular allergic disease: (1) to highlight IgE-mediated hypersensitivity; (2) to highlight non-IgE-mediated hypersensitivity; and (3) specialized ocular investigations.

1 To highlight IgE-mediated hypersensitivity, skin prick tests (SPTs) should be performed systematically for pollen, mites, animal dander, and alternaria (6, 7). Other allergens (cockroach, molds, and latex) or food allergens should be tested, according to the suspected exposure and patient’s medical history.

Serum-specific IgE measurements should be considered when SPTs are discordant with the medical history or contraindicated, or as an alternative to SPT to quantify specific IgE to naïve allergens and/or their purified components. The component-resolved diagnosis, based on the pure allergen molecules (microarray or recombinant allergen–specific IgE detection), may be helpful in the future for diagnosis in patients with multiple sensitizations (45). Total serum IgE is no longer considered indispensable for diagnosis, because normal values do not exclude a diagnosis of allergy. Alternatively, the multiple allergen screening test may be useful (9).

Conjunctival provocation test (CPT)/Conjunctival allergen challenge (CAC) can determine or confirm which allergen(s) triggers the ocular symptoms (22). The patient should be asymptomatic and the eye should not be inflamed. Standardized allergens are available (46), and systemic side-effects (generalized itching, bronchospasm, anaphylaxis) are rare. Conjunctival provocation test is useful to evaluate the specific conjunctival response in patients with negative SPT or specific IgE, but a positive clinical history of ocular allergy (47), as well as to evaluate the effect of anti-allergic treatments and specific immunotherapy (22).

2 To highlight a non-IgE-mediated hypersensitivity, it is necessary to perform the patch test using the European battery (48) and suspected cosmetics. Other batteries are used according to the patient history. It must be emphasized that eyelid skin is quite different from that of the back, as regards the depth of the epithelial and dermal layers. If a patch test is negative, a repeated open application test (ROAT) or use application test can be performed (49). If topical drugs are suspected, the patch tests for ocular drugs and ingredients in eye drops and ROAT can be performed.

3 Specialized ocular investigations are necessary when traditional allergy test results are negative. Conjunctival cytodiagnosis can assess conjunctival inflammation in the active phase and can be performed using different methods: tear cytology, conjunctival scraping, and brush cytology (a modification of the Cytobrush). Impression cytology is indicated to investigate epithelial cell pathology (50). The presence of eosinophils is highly indicative of allergic inflammation, while their absence does not exclude an allergic etiology. Total tear IgE levels can increase in patients with allergic conjunctivitis, suggesting that tear IgE measurement can help to diagnose allergic conjunctivitis (51). The tear-specific IgE assay is identical to that used for serum IgE measurement; however, there are no standardized reference parameters for the eye. A comparison between tear/serum IgE levels and a marker of serum transudation such as albumin may confirm local IgE production (52). However, the difficulty of tear collection, dilution, and the quantitative limits of the assay make CPT more appropriate to assess the specific conjunctival response.

The level of eosinophil cationic protein (ECP) in tears increases significantly in all forms of allergic conjunctivitis (53) and correlates with the severity of corneal involve-
Inflammatory conditions and Subacute and chronic infections

Tear film dysfunction (dry eye)

Differential diagnosis of ocular allergy

Table 4

<table>
<thead>
<tr>
<th>Condition</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tear film dysfunction (dry eye)</td>
<td>Dry eye is the result of decreased tear production or increased tear evaporation.</td>
</tr>
<tr>
<td>Dry eye</td>
<td>More common in adults and is associated with systemic autoimmune disorders or senescence. However, tear film dysfunction can occur at any age. Signs and symptoms include irritation, grittiness, burning, and foreign body sensation, but also itching. Dry eye may be worsened by various medications including oral antihistamines, yet it can occur concomitantly to allergy.</td>
</tr>
<tr>
<td>Subacute and chronic infections</td>
<td>In bacterial conjunctivitis, the discharge is usually purulent with morning crusting around the eyelids. Viral conjunctivitis is often seen in conjunction with a recent upper respiratory tract infection. Conjunctival hyperemia, chemosis, serous discharge, and corneal subepithelial opacities indicate a viral infection.</td>
</tr>
<tr>
<td>Chlamydial conjunctivitis</td>
<td>Characterized by a follicular persistent or chronic conjunctivitis.</td>
</tr>
<tr>
<td>Inflammatory conditions</td>
<td>Blepharitis is a common condition, characterized by eyelid margin hyperemia, ocular irritation, itching and discomfort caused by eyelid margin staphylococcal infection, meibomitis with or without seborrhea. Frequently associated with blepharitis and dry eye are seborrhea, psoriasis, atopic dermatitis, and acne rosacea. Ocular cicatricial pemphigoid, in the early stages, is a persistent conjunctivitis with subepithelial fibrosis at the internal canthus.</td>
</tr>
</tbody>
</table>

Inflammatory mediator measurements in tear fluid have been extensively used in ocular allergy either to find a ‘disease marker’, or to better understand the immune mechanisms involved and identify potential targets for therapeutic interventions. Multiplexed bead-based flow cytometry (31) and membrane or multiwell arrays (32) allow the simultaneous measurement of various mediators in a tear sample of few microliters, opening up further opportunities for diagnosis. Although several mediators can be detected, none is sufficiently standardized to be considered as a clear marker of ocular allergy and none of these techniques is standardized for the local use (50). Tear film evaluation is performed by vital staining tests to demonstrate the epithelial integrity and the tear film function. Fluorescein stains epithelial defects, whereas rose bengal and lissamine green stain dead and damaged epithelial cells. Tear film stability can be measured by the break-up time. The Schirmer test is universally performed to diagnose the dry eye syndrome by evaluating tear film production. In vivo confocal microscopy has been used to study several inflammatory and noninflammatory conditions, including severe ocular allergies (54, 55).

**Differential diagnosis**

Several clinical presentations may mimic the clinical features of hypersensitivity disorders of the ocular surface, including tear film dysfunction, subacute and chronic infections, and some autoimmune and inflammatory conditions (Table 4). These conditions should be considered by all physicians and must be confirmed by the ophthalmologist.

Milder forms of VKC may be confused with chronic perennial allergic conjunctivitis, phlyctenular keratoconjunctivitis, or trachoma (in endemic areas). Recurrent blepharitis with corneal involvement (ocular rosacea) can be confused with AKC or VKC. Mild cases of ocular cicatricial pemphigoid can mimic signs of AKC. Episcleritis and acute anterior uveitis are painful unilateral conditions that associate with autoimmune disorders.

**Treatment for ocular allergy**

The management of ocular allergy includes allergen avoidance, pharmacological treatment, immunotherapy, and patient education. The recommendations for allergen avoidance reported in the ARIA document should be followed (9), with the addition of wearing sunglasses to reduce direct ocular exposure to the airborne allergens. Cold compresses provide relief from symptoms (especially itching), and the use of lubricants (artiﬁcial tears) may improve the function of the ocular surface barrier. It is worth noting that most SAC and PAC patients treat themselves symptomatically or are treated by pharmacists or general practitioners (4).

**Anti-allergic medication**

Currently available topical drugs belong to several different pharmacological classes: antihistamines; mast cell stabilizers; mast cell stabilizers with antihistamine action, called ‘dual-acting’ agents; vasoconstrictors; nonsteroidal anti-inflammatory agents; corticosteroids; and calcineurin inhibitors. To minimize possible toxic effects of preservative compounds on the ocular surface, single-dose preservative-free eye drops should be used whenever possible in chronic forms of ocular allergy.

Topical antihistamines are competitive H1 receptor antagonists of varying speciﬁcity, potency, and duration of action. The ﬁrst-generation H1 antagonists, pheniramine and antazoline, have a long safety record, but are known for their burning sensation upon instillation, their rapid onset but also rapid disappearance of effects, and their limited potency (grade D). They are still available in association with vasoconstrictors in over-the-counter products. The second-generation H1 antagonists levocabastine and emedastine have a longer duration of action (4–6 h) and are better tolerated than their predecessors (grade D). Both drugs are effective and well tolerated also in pediatric patients (grade C). They can be used in combination with mast cell stabilizers as maintenance treatment throughout the allergy season.

Oral antihistamines have been proven effective in relieving nasal and conjunctival symptoms (9, 56) (grade C). Accord-
ing to ARIA, second-generation antihistamines have the same efficacy than their predecessors, with a low-sedating profile and lack of anticholinergic activity (9) (grade C). When symptoms are primarily ocular, topical antihistamines should be preferred over systemic ones. Eye drops provide faster relief of ocular symptoms than systemic agents. Combination therapy with second-generation oral antihistamine and topical agents has been shown to be superior to oral treatment alone (56, 57) (grade C).

Mast cell stabilizers inhibit degranulation by interrupting the normal chain of intracellular signals that results from the activation of the IgE receptor (59). Used prophylactically, they inhibit the release of preformed inflammatory mediators and the arachidonic acid cascade and are effective in reducing signs and symptoms of ocular allergy. Several agents are available for topical use, including sodium cromoglycate 2% and 4%, nedocromil 2%, lodoxamide 0.1%, spaglumic acid 4%, and pemiglumis 0.1% (not available in Europe) (60). They all require a preloading period (up to 2 weeks) and frequent installation (3–4 times/day), which sometimes results in poor compliance (56) (grade C).

Dual-action anti-allergic molecules azelastine, epinastine, ketotifen, and olopatadine (57) have the advantage of providing rapid relief from symptoms (owing to their antihistaminic effect) coupled with the long-term benefit of mast cell stabilization (57), making twice daily dosing possible (olopatadine 0.2% once a day is not available in Europe). Subtle distinctions between each of these drugs are likely to be reflected in differences in individual clinical outcomes. In patients with SAC, olopatadine, ketotifen, and epinastine were more effective than fluorometholone in preventing itching and hyperemia (61) (grade B).

Vasoconstrictors are alpha-adrenergic agonists approved for topical use in the relief of conjunctival redness, but have poor efficacy on other symptoms. Many of these products are marketed worldwide. Although they are well known and widely used, their short duration of action (2 h or less), significant stinging sensation, and tachyphylaxis limit their value when compared with the newer anti-allergic drugs (57) (grade D). Topical vasoconstrictors are not usually recommended because they are nonspecific and have no pharmacological action on the cascade of events underlying the allergic reaction.

The nonsteroidal anti-inflammatory drug (NSAID), ketorolac tromethamine 0.5%, is the only ophthalmic NSAID currently approved by the FDA for the relief of ocular itching in seasonal allergic conjunctivitis (62) (grade D). By blocking the synthesis of prostaglandins, in particular PGD₂, NSAIDs partially inhibit the cascade of events that follows mast cell activation. Other NSAIDs, such as diclofenac, may also have some effect in controlling acute symptoms of seasonal allergic and vernal conjunctivitis (63) (grade D). These drugs should be used with caution in patients with a history of NSAID intolerance.

Topical Corticosteroids should be avoided in SAC and PAC; however, their use is, at times, inevitable in VKC and AKC when the cornea is involved. Corticosteroids do not directly stabilize immune cell membranes and do not inhibit histamine release. However, they may modulate the mast cell response by inhibiting cytokine production and recruitment and activation of inflammatory cells. Thus, although they are not the first choice of therapy for ocular allergy, clinically, they are the most effective anti-inflammatory agents in active diseases. Topical fluorometholone, medrysone, loteprednol, rimexolone, and desonide eye drops, known as ‘soft’ corticosteroids, are the first choice in moderate inflammation (grade D). For severe allergic inflammation, prednisolone, dexamethasone, or betamethasone eye drops should be used, opting for the lowest dose and for the shortest duration of time. The therapeutic effects of the drugs, as well as the potential adverse effects (increased intraocular pressure, with a potential evolution toward glaucoma, cataract formation, bacterial, viral and fungal super-infections), must be monitored by an ophthalmologist, and the dose should be tapered slowly over several days. Hydrocortisone 1% cream on the eyelid skin is recommended for the treatment of severe acute eyelid eczema.

Even though nasal corticosteroids are not a first-line treatment for allergic conjunctivitis, in patients with rhinoconjunctivitis, nasal mometasone furoate (64) (grade A) and fluticasone furoate (65) (grade A) have been shown to improve the associated conjunctival symptoms. Although intranasal corticosteroids improve ocular symptoms, the involved mechanisms(s), probably related to nose-ocular reflex reduction, is unknown. There are limited data on ocular safety; however, the literature supports their use over several months as there is no considerable increase in the risk of ocular hypertension or glaucoma (66).

Calcineurin inhibitors have not been approved in Europe or the United States for the treatment of ocular allergy (approved only in Japan), and their use should be reserved to selected patients who are followed in referral centers. Several reports have demonstrated the clinical benefit of topical cyclosporine (CsA) 1–2% eye drops in the treatment of severe VKC and AKC patients, ameliorating the signs and symptoms without significant adverse effects (grade D) (67, 68). A 0.05% ophthalmic emulsion has been approved by the FDA for the treatment of dry eye syndrome. Topical CsA 0.05% was not more effective than placebo as a steroid-sparing agent in steroid-dependent VKC patients (69) (grade B), but was effective in the long-term prevention of VKC relapses when compared with topical ketotifen (70) (grade A). In Japan, CsA 0.1% aqueous ophthalmic solution was shown to be effective and safe in the treatment of a large population of VKC and AKC patients (71) (grade C).

Tacrolimus and pimecrolimus dermatological creams are both licensed for the treatment of moderate-to-severe atopic eyelid diseases (72). Although patients may be at risk of local infectious complications, tacrolimus 0.1% (73) (grade C) and 0.03% ointments (74) and 1% pimecrolimus (75) (grade A) are effective in the treatment for severe ocular allergies.

Specific immunotherapy (SIT), using either subcutaneous or sublingual administration and different dosing schedules, has been reported to be effective in the treatment of patients affected by SAC and PAC. In the majority of studies, patients were diagnosed with allergic rhinoconjunctivitis; only a few studies were performed in patients with SAC.

Table 6 Unmet needs in ocular allergy

The classification of ocular allergies is still unclear. Well-conducted epidemiological studies are needed to determine the real prevalence and severity of ocular allergy. Define the control and severity of ocular allergy and assess direct and indirect costs. Define phenotypes/genotypes in relation to disease heterogeneity, immune responses, and inflammation, and their relevance to the severity and control of ocular allergy by medications or immunotherapy. Define the role of allergens and panallergens in vernal keratoconjunctivitis and atopic keratoconjunctivitis. Specific mediator and cellular mechanisms associated with particular types of ocular allergy must be identified and should lead to new diagnostic tools and novel therapies. Novel treatments are needed to control symptoms in severe patients.

**Practical treatment for ocular allergy**

See Table 5.

**Conclusions and unmet needs**

This position paper summarizes the current view regarding classification, pathophysiology diagnosis, and treatment for ocular allergy. It also aims to stimulate the interest, comprehension, and further investigations in this almost forgotten field, for both allergists and ophthalmologists. For example, it is still not clear why the eye can be the only target organ, or why some patients suffer from severe untreatable or chronic forms (Table 6). Ocular allergy suffers from a lack of resources, attracts low numbers of scientists, and requires more basic research. Pharmacological and immunological research has identified new possibilities to modifying the allergic immune response. This progress will continue, be applied to the eye, and eventually lead to complete control of moderate to severe forms of ocular allergy.
